Charge/Discharge Protection Circuit for a Rechargeable Battery

5

The invention refers to a charge/discharge protection circuit for a rechargeable battery which is protected by a fusible link, where the rechargeable battery comprises a control logic which opens or closes a load switch depending on the magnitude of the battery voltage, the voltage on the charge/discharge terminals of the protection circuit and the charge/discharge current.

Such a protection circuit is known as an integrated circuit (IC) with the designation UCC 3952 of Texas Instruments Incorporated. This circuit monitors, among other things, the charge/discharge circuit voltage of the battery and disconnects from the battery via the load switch the charging device when charging and disconnects the load (e.g., a mobile transmitter) when discharging. In addition, the protection circuit monitors the discharge current via a current sensing resistor and opens the load switch when a limit is exceeded (of, e.g., 3 A).

20

The electric strength of the known protection circuit and the breakdown voltage of the load switch have to be designed for the highest (reasonably to be expected) applied voltage, which for example occurs when connecting a defective charging device or a

charging device which was intended for a battery with a higher than the actual voltage or a higher number of cells.

To achieve in an integrated circuit technology a high electric strength, respectively
5 breakdown voltage, large silicon areas and/or special technologies are necessary.
Alternatively, though the control logic can be provided with an electric strength
commensurate with the actual battery voltage, the load switch then needs to be
implemented as an external component with a correspondingly high breakdown voltage.

100% DECODED
15

The task of this invention is based on the requirement to create a charge/discharge
protection circuit of the above described type which in normal operation offers the usual
functions, whose electric strength, however, needs to be determined only by the actual
maximum battery voltage, and which therefore is economical and, when produced in an
integrated circuit technology, requires little real estate on an IC chip.

15
This task is inventively solved with a protection circuit of the above discussed type by
providing the control logic with an over-voltage detector. The over-voltage detector is
activated and closes a short-circuit switch when the over-voltage detector reaches a
fixed voltage limit which in turn depends on the electric strength of the protection circuit.
20 The closing of the short-circuit switch connects the battery terminals via a fusible link.

In the present context the terms "battery" and "battery voltage" stand for a rechargeable
current source or its potential, in particular also for a voltage source comprising only

DS01-036

one cell, e.g., a Lithium-Ion cell. It is well known that such voltage sources are typically provided for mobile telephones and are, therefore, subject to special safety rules.

Massive overcharging in particular must be reliably prevented because of the associated danger of explosion and fire hazard. This is achieved as proposed by the

5 present invention with a circuit technology with a significantly lower than required electric strength for the worst case condition. And that is accomplished by closing the short-circuit switch when an appropriate predetermined voltage limit is reached, with the resulting short circuit leading to the guaranteed destruction of the fusible link, thus protecting the battery from a dangerous current over-charge.

10 The proposed embodiment according to the invention makes it possible therefore to economically realize the protection circuit in standard sub-micro technology having a low break-down voltage. If desired, this allows the load switch to be integrated on the same chip with the other components of the protection circuit, whereas now it is frequently realized as a discrete component.

15 The over-voltage detector preferably receives as supply voltage the voltage via the opened load-current switch (claim 2). The voltage limit, at which the over-voltage detector responds, is defined in this case as the voltage just below the break-through voltage of the load-current switch.

20 Alternatively, the over-voltage detector can receive as supply voltage the difference between the voltage at the charge/discharge terminals and the voltage at the battery

contacts (claim 3). The voltage limit is then defined as that highest potential at which at least all functionally important circuit components still perform reliably.

When the voltage limit is exceeded it is preferred that the control logic close the 5 previously open load-current switch followed by the time-delayed closing of the short-circuit switch (claim 4). The reason why the load-current switch is open in the presently considered failure mode is that the protection circuit has determined that the maximally allowable load current for normal operation has been exceeded, and has accordingly opened the load-current switch. By closing the load-current switch when the voltage 10 limit is exceeded, dangerously high potentials are reduced via the load-current switch. However, now an inadmissibly high load current flows. This already can lead to the desired melting of the fusible link if the current is high enough. If the current is not high enough then the short-circuit switch will close after a delay time in the range of milliseconds or maximally of seconds and initiates thereby the destruction of the fusible 15 link.

The control logic, appropriately, receives a first supply voltage from the battery, and at least a second supply voltage from an auxiliary voltage source, such as a charged buffer capacitor, when the battery voltage is too low (claim 5). This assures in the 20 presently contemplated failure mode that the protection circuit is supplied with the necessary supply voltage to function until the fusible link is destroyed.

The over-voltage detector preferably includes a bistable flip-flop (claim 7) so that the closing of the short-circuit switch is initiated even when the predetermined voltage limit is exceeded for only a short time.

The protection circuit comprises a control logic, preferably in the form of an integrated circuit, and altogether designated 10. It compares battery voltage V_{batt} , reduced via resistive divider R_1 , R_2 , R_3 , using differential amplifiers D1 and D2 with an internally generated reference voltage V_{ref} . In the case of under-voltage the differential amplifier

5 D1 produces an output signal UV. In the case of over-voltage the differential amplifier D2 produces an output signal OV. Furthermore, the control logic compares the charge and the discharge current with a predetermined maximum value each. Towards that end differential amplifiers D3, respectively D4, compare the voltage V_{sense} as measured between load switch 3 and current sensing resistor 4, respectively the output voltage V_{out} at terminal 5, with the corresponding reference voltages which can be derived from V_{out} , respectively V_{sense} , through resistances R_4 , respectively R_5 , in series with constant current source I_1 and I_2 . Differential amplifiers D3, D4, deliver output signals OCC, OCD, respectively, when reaching the maximum charge or discharge current, respectively.

15 The output signals UV, OV, OCC, and OCD of differential amplifiers D1 to D4 are coupled via OR gate 11 to one of the inputs of AND gate 12, whose other input receives in normal operation a signal "H" from the output of inverter 13. The output signal V_L of AND gate 12 then controls the opening of load switch 3.

20 To monitor the potential across the opened load switch, over-voltage detector 14 (having the characteristic of a bistable flip-flop) receives the battery voltage V_{batt} and the voltage V_{sense} , respectively. Over-voltage detector 14 switches into a second stable state when a defined voltage limit is reached or is exceeded which is dependent upon

the break-down voltage of load switch 3. Over-voltage detector 14 delivers in this second state an output signal which sets via inverter 13 the second input of AND gate 12 to "L", thereby closing load switch 3 and removing the over-voltage. Delay-element 15 receives the same output signal and delivers to connector V_K a control signal after a 5 delay of typically several hundred milliseconds and which controls the closing of short-circuit switch 20, the latter connecting the battery terminals via fusible link 2. If a voltage source (for example, a defective charging device) connected to external terminals 5, 6 has not yet led to the destruction of fusible link 2 at this point in time, i.e., during the time delay, then fusible link 2 will be destroyed immediately through the high 10 short-circuit current delivered by Lithium-Ion cell 1. This reliably separates Lithium-Ion short-circuit current delivered by Lithium-Ion cell 1. This reliably separates Lithium-Ion 15 cell 1 from external terminals 5, 6.

The subsequent rise in potential will with great probability permanently render the protection circuit useless. This, however, is an intentional trade-off.

15 The dotted line indicates that the parts of control logic 10 may be located on an IC. Integrated on the same IC may also be load switch 3, and/or short-circuit switch 20, and/or fusible link 2.

20 Closing of short-circuit switch 20 leads to the immediate collapse of the outer supply voltage of the protection circuit. However, short-circuit switch 20 and load switch 3 must receive their control signal at least long enough until fusible link 2 is destroyed with certainty. This is achieved via buffer capacitor 16 which is placed between voltage

V_{batt} and a terminal V_{suppl} of the protection circuit. Buffer capacitor 16 is normally charged to the battery voltage via semiconductor switch 17 (indicated as a diode). If the outer supply voltage drops away then switch 17 opens and buffer capacitor 16 delivers for a sufficiently long time, via the dotted connection, the supply voltage for 5 over-voltage detector 14, delay-element 15, inverter 13, and AND gate 12.

Figure 2 shows an example of an embodiment of the over-voltage detector. Designations at the external terminals correspond to those of Fig. 1. Voltages V_{batt} and V_{sense} are applied to trigger elements 141, 142 via resistors R_{11} , R_{12} , respectively. The trigger elements are shown symbolically only as a serial connection of a zener and a back-biased diode. Trigger element 141 becomes conductive when the difference between V_{batt} and V_{sense} in the positive direction reaches its selected threshold, where the selected threshold is lower than the breakdown voltage of load switch 3. This causes NMOS transistor T1 to become conductive. The potential on its load resistor 15 R_{13} increases toward V_{batt} . The following Schmitt Trigger 143 produces from this a steeply sloped signal, which is applied to the first input of NAND gate 145. The output of NAND gate 145 thereupon switches to "H", thereby producing a rising clock signal Clk for the clock input of a following D-flip-flop 146, whose D input is tied to "H", whereby output Q also switches to "H". Output Q corresponds to the output of circuit 20 block 14 in Fig. 1.

If the difference between V_{batt} and V_{sense} reaches the predetermined voltage limit in the negative direction, then, in similar fashion, a voltage is produced via trigger element

DS01-036

142, NMOS transistor T2, and NMOS transistor T3, which then produces via second Schmitt-Trigger 144 and the second input of NAND gate 145 also a signal "H" at the output of D-flip-flop 145. NMOS transistor T3 functions in this case simply as a cascode-transistor to insure that the allowable drain-source voltage of transistor T1 is
5 not exceeded.

Figure 3 shows another example of an embodiment of the over-voltage detector 14 for a protection circuit in accordance with Fig. 1. Differing from the embodiment according to Fig. 2 but having in principle the same arrangement, the trigger elements are not supplied by V_{batt} and V_{sense} but by V_{common} and V_{sense} , i.e., the potential at
10 charge/discharge terminals 5, 6 when load switch 3 is opened. Otherwise the circuit uses the same elements as the circuit according to Fig. 2 and, therefore, also has the same reference numbers. However, it does not need a cascode transistor but requires PMOS in place of NMOS transistors.
15

In addition, a combination of the circuits according to Figures 2 and 3 can have advantages. For example, negative over-voltages could be implemented with the circuit according to Fig. 2, and positive over-voltages could be implemented with the circuit according to Fig. 3. As a further improvement, trigger elements 141 and 142 could be
20 modified so that their threshold voltages are, e.g., independent of temperature changes.
